Why nonparametrics?

Not always just interested in the mean of a (conditional) distribution.

- sometimes just interested in the distribution
- sometimes this is the first stage and we want to integrate
- sometimes want to do something semiparametric

In this section, we are interested in estimating the density  $f(\boldsymbol{x})$  under minimal assumptions.

Charlie Murry & Richard L. Sweeney

Let's start with the histogram

One of the more successful and popular uses of nonparametric methods is estimating the density or distribution function f(x) or F(x).

$$\hat{f}_{HIST}(x_0) = \frac{1}{N} \sum_{i=1}^{N} \frac{\mathbf{1}(x_0 - h < x_i < x_0 + h)}{2h}$$

- Divide the dataset into bins, count up fraction of observations in each bins.
- 2h is the length of a bin.

Let's rewrite the histogram estimator

$$\hat{f}_{HIST}(x_0) = \frac{1}{Nh} \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right)$$

Where 
$$K(z) = \frac{1}{2} \cdot \mathbf{1}(|z| < 1)$$

We can think of more general forms of K(z;h).

We call  $K(\cdot)$  a Kernel function and h the bandwidth. We usually assume

- (1) K(z) is symmetric about 0 and continuous.
- f(x) = 1,  $\int zK(z)dz = 0$ ,  $\int |K(z)|dz < \infty$ .
- $\text{ filther (a) } K(z)=0 \text{ if } |z| \geq z_0 \text{ for some } z_0 \text{ or } \\ \text{ (b) } |z|K(z) \rightarrow 0 \text{ as } |z| \rightarrow \infty.$
- $\bigcirc \int z^K(z)dz = \kappa$  where  $\kappa$  is a constant.

Defende

We call  $K(\cdot)$  a Kernel function and h the bandwidth. We usually assume

(1) K(z) is symmetric about 0 and continuous.

$$f$$
  $\int K(z)dz = 1$ ,  $\int zK(z)dz = 0$ ,  $\int |K(z)|dz < \infty$ .

- $\text{ filther (a) } K(z)=0 \text{ if } |z|\geq z_0 \text{ for some } z_0 \text{ or } \\ \text{ (b) } |z|K(z)\rightarrow 0 \text{ as } |z|\rightarrow \infty.$
- $\bigcirc \int z^K(z)dz = \kappa$  where  $\kappa$  is a constant.

Usually we choose a smooth, symmetric K. But a common nonsmooth choice: K(x)=(|x|<1/2) gives the *histogram* estimate.

# Mean and Variance of $\hat{f}(x_0)$

Assume that the derivative of f(x) exists and is bounded, and  $\int zK(z)dz=0$ Then the estimator has **bias** 

$$b(x_0) = E\left[\hat{f}(x_0)\right] - f(x_0) = \frac{1}{2}h^2f''(x_0)\int z^2K(z)dx$$

The variance of the estimator is

$$V\left[\hat{f}(x_0)\right] = \frac{1}{Nh}f(x_0)\int K(z)^2 dz \left\{+o(\frac{1}{Nh})\right\}$$

So, unsurprisingly, the bias is increasing in h, and the variance is decreasing in h.

#### Density Estimation Cross-

Example:

Auctions

parametric Regression

Multivariate Kernels Local linear

Bootstrap

Basis Expansions

Semiparametrics

References

- We want both bias and variance to be as small as possible, as usual.
- In parametric estimation, it is not a problem: they both go to zero as sample size increases.
- In nonparametric estimation reducing h reduces bias, but increases variance; how are we to make his trade off?
- Note that how we set h is going to be much more important than the choice of  $K(\cdot)$

# Mean Integrated Square Error

ullet Start with the *local* performance at  $x_0$ 

$$MSE\left[\hat{f}(x_0)\right] = E\left[\left(\hat{f}(x_0) - f(x_0)\right)^2\right]$$

• Calculate the integrated (as opposed to expected) squared error

$$\int \left( \hat{f}(x) - f(x) \right)^2 dx = \qquad \int \mathsf{bias}^2 \left( \hat{f}(x) \right) + \mathsf{var} \left( \hat{f}(x) \right) dx$$

• Simple approximate expression (symmetric order 2 kernels):

$$(bias)^2 + variance = Ah^4 + B/nh$$

with 
$$A = \int (f''(x))^2 (\int u^2 K)^2 / 4$$
 and  $B = f(x) \int K^2$

# Optimal bandwidth

• The AMISE is

$$Ah^4 + B/nh$$

• Minimize by taking the FOC

$$h_n^* = \left(\frac{B}{4An}\right)^{1/5}$$

- bias and standard error are both in  $n^{-2/5}$
- and the AMISE is  $n^{-4/5}$ —not 1/n as it is in parametric models.
- But: A and B both depend on K (known) and f(y) (unknown), and especially "wiggliness"  $\int (f'')^2$  (unknown, not easily estimated). Where do we go from here?

$$h* = \delta \left( \int f''(x_0)^2 dx_0 \right)^{-0.2} N^{-0.2}$$

where  $\delta$  depends on the kernel used (Silverman 1986) [these  $\delta$ 's are given in the kernel table]

Note the "optimal" kernel is Epanechnikov, although the difference is small.

## Cross-validation

 $\bullet$  General concept in the whole of nonparametrics: choose h to minimize a criterion CV(h) that approximates

$$AMISE(h) = \int E(\hat{f}_n(x) - f(x))^2 dx.$$

- Usually programmed in metrics software. If you can do it, do it on a subsample, and rescale.
- CV tries to measure what the expected out of sample (OOS or EPE) prediction error of a new never seen before dataset.
- The main consideration is to prevent overfitting.
  - In sample fit is always going to be maximized by the most complicated model.
  - OOS fit might be a different story.
  - ie 1-NN might do really well in-sample, but with a new sample might perform badly.

Sample Splitting/Holdout Method and CV

Cross Validation is actually a more complicated version of sample splitting that is one of the organizing principles in machine learning literature.

Training Set This is where you estimate parameter values.

Validation Set This is where you choose a model- a bandwidth h or tuning parameter  $\lambda$  by computing the error.

Test Set You are only allowed to look at this after you have chosen a model.

Only Test Once: compute the error again on fresh data.

- Conventional approach is to allocate 50-80% to training and 10-20% to Validation and Test.
- Sometimes we don't have enough data to do this reliably.

### Cross Validation

- Main advantage of cross validation is that we use all of the data in both estimation and in validation.
  - For our purposes validation is mostly about choosing the right bandwidth or tuning parameter.
- We have much lower variance in our estimate of the OOS mean squared error.
  - Hopefully our bandwidth choice doesn't depend on randomness of splitting sample.

Test Data

- In Statistics/Machine learning there is a tradition to withhold 10% of the data as Test Data.
- This is completely new data that was not used in the CV procedure.
- The idea is to report the results using this test data because it most accurately simulates true OOS performance.
- We don't do much of this in economics. (Should we do more?)

Multivariate Local linear

# Higher-Order Kernels

- K of order r iff  $\int x^j K(x) dx = 0$  for j < r and  $\int x^r K(x) dx \neq 0$ . Try r > 2?
- The beauty of it: bias in  $h^r$  if f is at least  $C^r$ ... so AMISE can be reduced to  $n^{-r/(2r+1)}$ , almost  $\sqrt{n}$ -consistent if r is large.
- But gives wiggly (and sometimes negative) estimates  $\rightarrow$  leave them to theorists.

Since now we have estimated the density with

$$\hat{f}_n(x) = \frac{1}{nh} \sum_{i=1}^n K\left(\frac{x - x_i}{h}\right),$$

Estimation

Since now we have estimated the density with

$$\hat{f}_n(x) = \frac{1}{nh} \sum_{i=1}^n K\left(\frac{x - x_i}{h}\right),$$

a natural idea is to integrate; let  $\mathcal{K}(x) = \int_{-\infty}^x K(t)dt$ , try

$$\hat{F}_n(y) = \frac{1}{n} \sum_{i=1}^n \mathcal{K}\left(\frac{y - y_i}{h}\right)$$

as a reasonable estimator of the cdf in y.

Charlie Murry & Richard L Sweeney

Cross-

Validation

Multivariate Local linear

## Back to the CDF cont...

Reasonable estimator of the cdf in y?

$$\hat{F}_n(y) = \frac{1}{n} \sum_{i=1}^n \mathcal{K}\left(\frac{y - y_i}{h}\right)$$

Very reasonable indeed:

- when  $n \longrightarrow \infty$  and h goes to zero (at rate  $n^{-1/3}$ ...) it is consistent at rate  $\sqrt{n}$
- it is nicely smooth
- by construction it accords well with the density estimator
- ... it is a much better choice than the empirical cdf.

Example application: Auctions

• Why auctions?

- Great introduction to structural approach. Arguably the most successful application.
- Auctions are an example of a game with assymetric information: participants know the primitives of the game, but do not know their rivals exact valuations.
- By imposing rationality/ profit maximization, we can recover the distribution of values.
- Can then run counterfatuals
- Example: Asker (AER 2008) stamp cartel

For more detail, check out Chris Conlon's slides in this folder, or John Asker's PhD lecture notes.

Example: Auctions

Auctions

parametric Regression

Multivariate Kernels Local linear

Bootstrap

Basis Expansions

Semiparametrics

References

Let's consider the first price sealed bid (FPSB) auction

- ullet bidders have **private information** (or type) scalar rv  $X_i$  with realization  $x_i$
- signals are informative: dE[U|x]/dx>0
- ullet given their signal, they make a bid  $b_i$
- ullet if its the highest bid, recieve utility  $[U|x_i,x_{-i}]-b_i$
- else get 0
- note that if we assume values are independent, we get  $E[U|x_i,x_{-i}]=E[U|x_i]$

This introduces a tradeoff in first price auctions: Increasing the bid increases the probability of winning; but reduces your net utility from the object.

Semiparametric

References

Denote the equilibrium bid as  $B_i$ , with realizations  $b_i$ 

Perfect Bayes Nash equilibrium:

$$\max_{\tilde{b}} \left( E\left[ U_i | X_i = x_i \right] - b, \max_{j \in N_{-i}} B_j \le \tilde{b} \right)$$

$$Pr\left(max_{j\in N_{-i}}B_{j}\leq \tilde{b}|X_{i}=x_{i}\right)$$

See Athey and Haile or Krishna for an accessible derivation.

### Can find bid as a function of primitives

$$v(x_i, \mathbf{x_i}; N) = b_i + \frac{G_{M_i|B_i}(b_i|b_i; N)}{g_{M_i|B_i}(b_i|b_i; N)}$$

where  $G_{M_i|B_i}$  and  $g_{M_i|B_i}$  are the CDF and PDF of the max bids given  $b_i$  and N

- we are typically interested in the LHS
- RHS is stuff we can observe or compute
- nice linear structure makes this easy to work with
- Guerre, Perrigne and Vuong (2000): can leverage assumption of equilibrium best response and invertibility of b to recover v

Deferences

[Assumption: FPSB with symmetric IPV]

1 Leverage independence assumption:

$$G_{M_i|B_i}(m_i|b_i; N) = G_{M_I|n}$$
  
=  $Pr(max_{j \neq i}B_j \leq m_i|n)$ 

2 Value equation becomes

$$u = b + \frac{G_B(b|n)}{(n-1)g_B(b|n)}$$

where  $G_B$  and  $g_B$  are now the marginal distribution of equilibrium bids and the densities in n bidder auctions

### Bias Variance Decomposition

We can decompose any estimator into two components

$$\underbrace{E[(y-\hat{f}(x))^2]}_{MSE} = \underbrace{\left(E[\hat{f}(x)-f(x)]\right)^2}_{Bias^2} + \underbrace{E\left[\left(\hat{f}(x)-E[\hat{f}(x)]\right)^2\right]}_{Variance}$$

- In general we face a tradeoff between bias and variance.
- In k-NN as k gets large we reduce the variance (each point has less influence) but we increase the bias since we start incorporating far away and potentially irrelevant information.
- In OLS we minimize the variance among unbiased estimators assuming that the true f is linear and using the entire dataset.

## Curse of Dimensionality

Take a unit hypercube in dimension p and we put another hypercube within it that captures a fraction of the observations r within the cube

- Since it corresponds to a fraction of the unit volume, r each edge will be  $e_p(r) = r^{1/p}$ .
- $e_{10}(0.01)=0.63$  and  $e_{10}(0.1)=0.80$ , so we need almost 80% of the data to cover 10% of the sample!
- If we choose a smaller r (include less in our average) we increase variance quite a bit without really reducing the required interval length substantially.

# Curse of Dimensionality

Don't worry, it only gets worse:

$$d(p, N) = \left(1 - \left(\frac{1}{2}\right)^{1/N}\right)^{1/p}$$

- d(p, N) is the distance from the origin to the closest point.
- N=500 and p=10 means d=0.52 or that the closest point is closer to the boundary than the origin!
- Why is this a problem?
- In some dimension nearly every point is the closest point to the boundary –
   when we average over nearest neighbors we are extrapolating not interpolating.

Semiparametric

References

What minimizes MSE?

$$f(x_i) = E[Y_i|X_i]$$

- Seems simple enough (but we are back where we started).
- How do we compute the expectation ?
- k-NN tries to use local information to estimate conditional mean
- OLS uses entire dataset and adds structure  $y = x\beta$  to the problem.
- A natural middleground point is to use a smoother that weights "close" observations more than "far" ones.

Consider the following local weighted average estimator:

$$\hat{m}(x_0) = \sum_{i=1}^{N} w_{i0,h} y_i$$

where  $w_{i0,h} = w(x_i, x_0, h)$  and  $\sum_i w_{i0,h} = 1$ .

## Common weights

Consider the following local weighted average estimator:

$$\hat{m}(x_0) = \sum_{i=1}^{N} w_{i0,h} y_i$$

where  $w_{i0,h} = w(x_i, x_0, h)$  and  $\sum_i w_{i0,h} = 1$ .

Rearranging, can see that OLS uses the following weights

$$\hat{m}_{OLS}(x_0) = \sum_{i=1}^{N} \left\{ \frac{1}{N} + \frac{(x_0 - \bar{x})(x_i - \bar{x})}{\sum_{j} (x_j - \bar{x})^2} \right\} y_i$$

CT note that these weights can actually *increase* with the distance between  $x_0$  and  $x_i!$  (for example if  $x_i>x_0>\bar x$  )

Charlie Murry & Richard L. Sweeney

Nonparametric Regression

Multivariate Local linear

# k-NN is simply a running average

$$\hat{m}_k(x_0) = \frac{1}{k} (y_{i-(k-1)/2} + \dots + y_{i+(k-1)/2})$$

Can immediately see that this will not be great at the end points.

For the smallest and largest x, the average is one sided. This is the **boundary** problem.

# Nonparametric Regression

Of course, we could also average all the observations within some bandwidth  $\boldsymbol{h}$  Nadaraya-Watson:

$$\hat{m}_n(x) = \frac{\sum_{i=1}^n y_i K\left(\frac{x-x_i}{h}\right)}{\sum_{i=1}^n K\left(\frac{x-x_i}{h}\right)}.$$

where  $K(\cdot)$  is a kernel weighting function as above.

Again, bias in  $h^2$  and variance in 1/nh if  $p_x = 1$ .

Density Estimation

Cross-Validation

Non-

parametric Regression

Multivariate Kernels Local linear

Bootstrap

Basis Expansions

Semiparametrics

References

Plug-in estimates work badly here.

In most cases leave one out cross-validation is feasible

Can be shown that this amounts to

$$\min_{h} CV(h) = \sum_{i=1}^{N} \left( \frac{y_i - \hat{m}(x_i)}{1 - \left[ w_{ii,h} / \sum_{j} w_{ji}, h \right]} \right)^2$$

So not that hard: for each h, only need to compute one weighted average  $\hat{m}(x_i)$  for each N.

### Silverman's Table

Silverman (1986 book) provides a table illustrating the difficulty of kernel estimation in high dimensions. To estimate the density at 0 of a N(0,1) with a given accuracy, he reports:

Dimensionality Required	Sample Size
1	4
2	19
5	786
7	10,700
10	842,000

Not to be taken lightly... in any case convergence with the optimal bandwidth is in  $n^{-2/(4+p_y)}$  now—and Silverman's rule of thumb for choosing  $h_n^*$  must be adapted too.

Charlie Murry & Richard L. Sweeney

Multivariate

Local linear

### Back to one dimesion I

We can interpret the standard kernel estimator as estimating a constant regressino function q(x) = m

where

$$\hat{m} = \arg\min_{m_0} \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right) \cdot (y_i - m_0)^2$$

Taking the FOC, we see that this yields

$$\hat{g}(x) = \hat{m} = \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right) \cdot y_i / \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right)$$

Local Linear Regression I

This suggests other functions instead of constants (that is why we're interested in this regression in the first place!)

A natural option is local linear regression:

$$m(x) = \alpha + \beta(x - x_0)$$

where

$$(\hat{\alpha}, \hat{\beta}) = \arg\min_{m_0} \sum_{i=1}^{N} K\left(\frac{x_i - x_0}{h}\right) \cdot (y_i - \alpha + \beta(x_i - x_0))^2$$

#### Charlie Murry & Richard L. Sweeney

Multivariate

Local linear

### Local Linear Regression II

### Advantages:

- the bias becomes 0 if the true m(x) is linear.
- the coefficient of  $(x x_i)$  estimates m'(x).
- behaves better in "almost empty" regions.

Disadvantages: hardly any, just do it! How?

Charlie Murry & Richard L. Sweeney

Multivariate

Local linear

# Example from Cameron and Trivedi

As an illustration, consider data generated from the model

$$y_i = 150 + 6.5x_i - 0.15x_i^2 + 0.001x_i^3 + \varepsilon_i, \quad i = 1, ..., 100,$$
  
 $x_i = i,$   
 $\varepsilon_i \sim \mathcal{N}[0, 25^2].$  (9.17)

The mean of v is a cubic in x, with x taking values  $1, 2, \dots, 100$ , with turning points at x = 20 and x = 80. To this is added a normally distributed error term with standard deviation 25.

The Housing Market Impacts of Shale Gas Development

By Lucija Muehlenbachs, Elisheba Spiller, and Christopher Timmins\*

Using data from Pennsylvania and an array of empirical techniques to control for confounding factors, we recover hedonic estimates of property value impacts from nearby shale gas development that vary with water source, well productivity, and visibility. Results indicate large negative impacts on nearby groundwater-dependent homes, while piped-water-dependent homes exhibit smaller positive impacts. suggesting benefits from lease payments. Results have implications for the debate over regulation of shale gas development. (JEL L71, O35, O53, R31)

# Empirical Strategy: DD

In deriving our empirical specification based on the preceding intuition, we begin by considering the price of house i at time t as a function of all well pads (k = 1, 2, ...K), a house fixed effect  $(\mu_i)$ , a fixed effect that varies with both geography (i.e., either county or census tract) and year  $(\nu_{it})$ , and a temporal fixed effect indicating the quarter  $(q_t)$ :

(2) 
$$\ln P_{it} = \alpha_0 + \sum_{k=1}^{K} \rho_{ik} w_{kt} + \mu_i + \nu_{it} + q_t + \epsilon_{it},$$

where k indexes the well and K is the total number of wells in Pennsylvania;  $w_{kt} = 1$ if well pad k has been drilled by time t (in a sensitivity analysis we differentiate between wells that are merely drilled and actually producing); and  $\rho_{ik}$  translates the presence of well  $w_{kt}$  into an effect on house price based on its proximity. We can

## Bootstrap and Delta Method

- We know how to construct confidence intervals for parameter estimates:  $\hat{\theta}_k \pm 1.96 SE(\hat{\theta}_k)$
- Often we are asked to construct standard errors or confidence intervals around model outputs that are not just parameter estimates: ie:  $g(x_i, \hat{\theta})$ .
- Sometimes we can't even write  $g(x_i, \theta)$  as an explicit function of  $\theta$  ie:  $\Psi(g(x_i, \theta), \theta) = 0$ .
- Two options:
  - Delta Method
  - 2 Bootstrap

Delta Method

Delta method works by considering a Taylor Expansion of  $q(x_i, \theta)$ .

$$g(z) \approx g(z_0) + g'(z_0)(z - z_0) + o(||z - z_0||)$$

Assume that  $\theta_n$  is asymptotically normally distributed so that:

$$\sqrt{n}(\theta_n - \theta_0) \sim N(0, \Sigma)$$

Then we have that

$$\sqrt{n}(g(\theta_n) - g(\theta_0)) \sim N(0, D(\theta)' \Sigma D(\theta))$$

Where  $D(\theta) = \frac{\partial g(x_i, \theta)}{\partial \theta}$  is the Jacobian of g with respect to theta evaluated at  $\theta$ . We need a to be continuously differentiable around the center of our expansion  $\theta$ .

Charlie Murry & Richard L. Sweeney

Density Estimation

## Delta Method: Examples

Start with something simple:  $Y=\overline{X}_1\cdot\overline{X}_2$  with  $(X_{1i},X_{2i})\sim IID$ . We know the CLT applies so that:

$$\sqrt{n} \begin{pmatrix} \overline{X}_1 - \mu_1 \\ \overline{X}_2 - \mu_2 \end{pmatrix} \quad \sim N \begin{bmatrix} \begin{pmatrix} 0 \\ 0 \end{pmatrix}, \Sigma \end{bmatrix}$$

The Jacobian is just  $D(\theta) = \begin{pmatrix} \frac{\partial g(\theta)}{\partial \theta_1} \\ \frac{\partial g(\theta)}{\partial \theta_2} \end{pmatrix} = \begin{pmatrix} \mu_2 \\ \mu_1 \end{pmatrix}$  So.

$$V(Y) = D(\theta)' \Sigma D(\theta) = \begin{pmatrix} \mu_2 & \mu_1 \end{pmatrix} \begin{pmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{21} & \sigma_{22} \end{pmatrix} \begin{pmatrix} \mu_2 \\ \mu_1 \end{pmatrix}$$
$$\sqrt{n} (\overline{X}_1 \overline{X}_2 - \mu_1 \mu_2) \sim N(0, \mu_2^2 \sigma_{11}^2 + 2\mu_1 \mu_2 \sigma_{12} + \mu_1^2 \sigma_{22}^2)$$

Sweeney

## Delta Method: Logit

Think about a simple logit:

$$P(Y_i = 1|X_i) = \frac{\exp^{\beta_0 + \beta_1 X_i}}{1 + \exp^{\beta_0 + \beta_1 X_i}}$$
$$P(Y_i = 0|X_i) = \frac{1}{1 + \exp^{\beta_0 + \beta_1 X_i}}$$

Remember the "trick" to use GLM (log-odds):

$$\log P(Y_i = 1|X_i) - \log P(Y_i = 0|X_i) = \beta_0 + \beta_1 X_i$$

- Suppose that we have estimated  $\hat{\beta}_0, \hat{\beta}_1$  via GLM/MLE but we want to know the confidence interval for the probability:  $P(Y_i = 1 | X_i, \hat{\theta})$
- The derivatives are a little bit tricky, but the idea is the same.
- This is what STATA should be doing when you type: mfx, compute

### Nonparametrics Charlie Murry &

## Richard L. Sweeney

Local linear

Bootstrap

Delta Method: Learning example

Often we have a nonlinear model that we transform and estimate linearly. Here is an example on learning curves from Eric Zivot.

**Example 2** Estimation of Generalized Learning Curve

Consider the generalized learning curve (see Berndt, 1992, chapter 3)

$$C_t = C_1 N_t^{\alpha_c/R} Y_t^{(1-R)/R} \exp(u_t)$$

where

 $C_t$  = real unit cost at time t

 $N_t$  = cumulative production up to time t

production in time t

73 / 110

Intuition: Learning is proxied by cumulative production.

• If the learning curve effect is present, then as cumulative production (learning) increases real unit costs should fall.

• If production technology exhibits constant returns to scale, then real unit costs should not vary with the level of production.

 If returns to scale are increasing, then real unit costs should decline as the level of production increases. The generalized learning curve may be converted to a linear regression model by taking logs:

by taking logs: 
$$\ln C_t \ = \ \ln C_1 + \left(\frac{\alpha_c}{R}\right) \ln N_t + \left(\frac{1-R}{R}\right) \ln Y_t + u_t$$

 $= \beta_0 + \beta_1 \ln N_t + \beta_2 \ln Y_t + u_t$ 

 $\beta_2 = (1-R)/R$ 

 $\mathbf{x}_t = (1, \ln N_t, \ln Y_t)'.$ 

 $\beta_0 = \ln C_1$  $\beta_1 = \alpha_c/R$ 

 $= \mathbf{x}_t' \boldsymbol{\beta} + u_t$ 

where

The learning curve parameters may be recovered using

$$egin{array}{ll} lpha_c &=& rac{eta_1}{1+eta_2} = g_1(eta) \ R &=& rac{1}{1+eta_2} = g_2(eta) \end{array}$$

$$\alpha_c = \frac{\beta_1}{1 + \beta_2} = g_1$$

$$\hat{oldsymbol{eta}} \; = \; (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} \stackrel{p}{
ightarrow} oldsymbol{eta}$$

$$\beta = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} \stackrel{P}{\to} \beta$$

$$\hat{oldsymbol{eta}}$$
  $\hat{oldsymbol{eta}}$ 

provided  $\beta_2 \neq -1$ .

$$\hat{\boldsymbol{\beta}} \stackrel{\sim}{\sim} N(\boldsymbol{\beta}, \hat{\sigma}^2(\mathbf{X}'\mathbf{X})^{-1})$$
 Then from Slutsky's Theorem 
$$\hat{\alpha}_{\alpha} = \frac{\hat{\beta}_1}{\hat{\beta}_1} \stackrel{p}{\rightarrow} \frac{\beta_1}{\hat{\beta}_1} = \alpha_{\alpha}$$

$$\hat{m{eta}} \stackrel{\sim}{\sim} N(m{eta}, \hat{\sigma}^2(\mathbf{X}'\mathbf{X})^{-1})$$
 Then from Slutsky's Theorem

Then from Slutsky's Theorem 
$$\hat{\alpha}_{c} = \frac{\hat{\beta}_{1}}{1+\hat{\beta}_{2}} \xrightarrow{p} \frac{\beta_{1}}{1+\beta_{2}} = \alpha_{c}$$
 
$$\hat{R} = \frac{1}{1+\hat{\beta}_{2}} \xrightarrow{p} \frac{1}{1+\beta_{2}} = R$$

 $\hat{eta} \stackrel{t=1}{\tilde{\beta}} N(eta, \hat{\sigma}^2(\mathbf{X}'\mathbf{X})^{-1})$ 

 $\hat{\sigma}^2 = n^{-1} \sum_{t=0}^{n} (y_t - \mathbf{x}_t' \hat{\boldsymbol{\beta}})^2 \stackrel{p}{\to} \sigma^2$ 

Least squares gives consistent and asymptotically normal estimates

We can use the delta method to get the asymptotic distribution of  $\hat{\eta} =$  $(\hat{\alpha}_c,\hat{R})'$ :

$$\begin{pmatrix}
\hat{\alpha}_c, R)' : \\
\begin{pmatrix}
\hat{\alpha}_c \\
\hat{R}
\end{pmatrix} = \begin{pmatrix}
g_1(\hat{\beta}) \\
g_2(\hat{\beta})
\end{pmatrix}$$

$$\stackrel{A}{\sim} N\left(\mathbf{g}(\beta), \left(\frac{\partial \mathbf{g}(\hat{\beta})}{\partial \beta'}\right) \hat{\sigma}^2(\mathbf{X}'\mathbf{X})^{-1} \left(\frac{\partial \mathbf{g}(\hat{\beta})}{\partial \beta'}\right)'\right)$$

 $\frac{\partial \mathbf{g}(\boldsymbol{\beta})}{\partial \boldsymbol{\beta}'} = \begin{pmatrix} \frac{\partial g_1(\boldsymbol{\beta})}{\partial \beta_1} & \frac{\partial g_1(\boldsymbol{\beta})}{\partial \beta_2} & \frac{\partial g_1(\boldsymbol{\beta})}{\partial \beta_3} \\ \frac{\partial g_2(\boldsymbol{\beta})}{\partial \beta_1} & \frac{\partial g_2(\boldsymbol{\beta})}{\partial \beta_2} & \frac{\partial g_2(\boldsymbol{\beta})}{\partial \beta_2} \end{pmatrix}$ 

 $= \begin{pmatrix} 0 & \frac{1}{1+\beta_2} & \frac{-\beta_1}{(1+\beta_2)^2} \\ 0 & 0 & \frac{-1}{(1+\beta_2)^2} \end{pmatrix}$ 

where

Murry & Richard L. Sweeney

Multivariate Local linear

### Bootstrap

Charlie

### Delta Method: Some Failures

But we need to be careful. Suppose that  $\theta \approx 0$  and

- q(x) = |X|
- q(x) = 1/X
- $q(x) = \sqrt{X}$

These situations can arise in practice when we have weak instruments or other problems.

Nonparametrics Charlie

Murry & Richard L. Sweeney • Bootstrap takes a different approach.

• Instead of estimating  $\hat{\theta}$  and then using a first-order Taylor Approximation...

• What if we directly tried to construct the sampling distribution of  $\hat{\theta}$ ?

## Bootstrap II

- Data  $(X_1, \ldots, X_n) \sim P$  are drawn from some measure P
  - We can form a nonparametric estimate  $\hat{P}$  by just assuming that each  $X_i$  has weight  $\frac{1}{n}$ .
- We can then simulate a new sample  $X^* = (X_1^*, \dots X_n^*) \sim \hat{P}$ .
  - ullet Easy: we take our data and construct n observations by sampling with replacement
- Compute whatever statistic of  $X^*$ ,  $S(X^*)$  we would like.
  - Could be the OLS coefficients  $\beta_1^*, \ldots, \beta_k^*$ .
  - Or some function  $\beta_1^*/\beta_2^*$ .
  - Or something really complicated: estimate parameters of a game  $\hat{\theta}^*$  and now find Nash Equilibrium of the game  $S(X^*, \hat{\theta}^*)$  changes.
- Do this B times and calculate at  $Var(S_b)$  or  $CI(S_1, \ldots, S_b)$ .

Semiparametric

References

• Linear predictor  $\beta = E[X_i X_i']^{-1} E[X_i Y_i]$ 

- Sample  $\{(Y_i, X_i)\}_{i=1}^N$
- OLS:  $\hat{\beta}_{ols} = [\sum_{i=1}^{N} X_i X_i']^{-1} [\sum_{i=1}^{N} X_i Y_i]$
- To get the variance, resample with replacement B times and calculate  $\hat{\beta}_{ols,b} = [\sum_{j=1}^N X_j X_j']^{-1} [\sum_{j=1}^N X_j Y_j]$
- Now an estimate of the variance is just

$$V(\beta_{ols}) = \frac{1}{B} \sum_{b}^{B} (\hat{\beta}_{ols,b} - \bar{\beta}_{ols,b}) \cdot (\hat{\beta}_{ols,b} - \bar{\beta}_{ols,b})'$$

Bootstrap: Variants I

The bootstrap I have presented is sometimes known as the nonparametric bootstrap and is the most common one.

Parametric Bootstrap instead of bootstrapping pairs  $(Y_i, X_i)$ , we can bootstrap the residuals.

- First estimate  $\hat{\beta}_{ols}$  by OLS
- Get residuals  $\hat{\epsilon}_i = Y_i X_i' \hat{\beta_{ols}}$
- For b=1,...,B, resample N residuals  $\hat{\epsilon}_i$
- Predict a new  $Y_{b,j} = X_j' \hat{eta}_{ols} + \hat{\epsilon}_{b,j}$
- Estimate with OLS and proceed as before.

### Bootstrap

## Bootstrap: Bias Correction

The main idea is that  $\hat{\theta}^{1*}, \dots, \hat{\theta}^{B*}$  approximates the sampling distribution of  $\hat{\theta}$ . There are lots of things we can do now:

• We already saw how to calculate  $Var(\hat{\theta}^{1*}, \dots, \hat{\theta}^{B*})$ .

$$\frac{1}{B-1} \sum_{b=1}^{B} (\hat{\theta}_{(b)}^* - \overline{\theta^*})^2$$

- Calculate  $E(\hat{\theta}_{(1)}^*, \dots, \hat{\theta}_{(B)}^*) = \overline{\theta^*} = \frac{1}{B} \sum_{b=1}^B \hat{\theta}_{(b)}^*$ .
  - We can use the estimated bias to bias correct our estimates

$$Bias(\hat{\theta}) = E[\hat{\theta}] - \theta$$
$$Bias_{bs}(\hat{\theta}) = \overline{\theta^*} - \hat{\theta}$$

Recall 
$$\theta = E[\hat{\theta}] - Bias[\hat{\theta}]$$
:

$$\hat{\theta} - Bias_{hs}(\hat{\theta}) = \hat{\theta} - (\overline{\theta^*} - \hat{\theta}) = 2\hat{\theta} - \overline{\theta^*}$$

- Correcting bias isn't for free variance tradeoff!
- Linear models are (hopefully) unbiased, but most nonlinear models are consistent bett110

## Bootstrap: Confidence Intervals

There are actually three ways to construct bootstrap CI's:

- $\textbf{ 1} \text{ Obvious way: sort } \hat{\theta}^* \text{ then take } CI: [\hat{\theta}^*_{\alpha/2}, \hat{\theta}^*_{1-\alpha/2}].$
- 2 Asymptotic Normal:  $CI: \hat{\theta} \pm 1.96 \sqrt{V(\hat{\theta}^*)}$ . (CLT).
- 3 Better Way: Use a pivotal statistic that you know the distribution of.

Bootstrap CI: percentile t method

- Instead of estimating  $\theta_b$  for each bootstrap sample, estimate the t-statistic  $t^b = (\hat{\theta}^b \hat{\theta})/s_{\hat{\theta}ba}$ , where  $\hat{\theta}$  is the original estimate.
- The empirical distribution of  $t^b$  can then be used to approximate the **known** t-distribution (which has nothing to do with our data)
- Let  $t^b_{[1-\alpha/2]}$  and  $t^b_{[\alpha/2]}$  denote the lower and upper  $\alpha/2$  quintiles of this distribution.
- A confidence interval can then be constructed as

$$\left(\hat{\theta} - t^b_{[1-\alpha/2]} \times \hat{s}_{\hat{\theta}}, \hat{\theta} + t^b_{[\alpha/2]} \times \hat{s}_{\hat{\theta}}\right)$$

## Bootstrap: Why do people like it?

- Econometricians like the bootstrap because under certain conditions it is higher order efficient for the confidence interval construction (but not the standard errors).
  - Intuition: because it is non-parametric it is able to deal with more than just the first term in the Taylor Expansion (actually an Edgeworth Expansion).
  - Higher-order asymptotic theory is best left for real econometricians!
- Practitioner's like the bootstrap because it is easy.
  - If you can estimate your model once in a reasonable amount of time, then you
    can construct confidence intervals for most parameters and model predictions.

### Bootstrap: When Does It Fail?

- Bootstrap isn't magic. If you are constructing standard errors for something that isn't asymptotically normal, don't expect it to work!
- The Bootstrap exploits the notion that your sample is IID (by sampling with replacement). If IID does not hold, the bootstrap may fail (but we can sometimes fix it!).
- Bootstrap depends on asymptotic theory. In small samples weird things can happen. We need  $\hat{P}$  to be a good approximation to the true P (nothing missing).

Bootstrap vs Delta Method

- Delta Method works best when working out Jacobian  $D(\theta)$  is easy and statistic is well approximated with a linear function (not too curvy).
- I would almost always advise Bootstrap unless:
  - Delta method is trivial e.g.:  $\beta_1/\beta_2$  in linear regression.
  - Computing model takes many days so that 10,000 repetitions would be impossible.
- Worst case scenario: rent time on Amazon EC2!
  - I "bought" over \$1,000 of standard errors recently.
- But neither is magic and both can fail!

### CI's for Kernel Smoothers

- Return to the theme of these slides: Estimating a nonparametric regression function.
- For kernel regression, you need to present CI's pointwise.
  - CT recommend presenting CIs for  $f(x_0)$  for the first nine deciles of x
- If we ignore the bias  $b(x_0)$  inherent in  $\hat{m}(x_0)$  then,

$$m(x_0) \in \hat{m}(x_0) \pm 1.96 \sqrt{\frac{1}{Nh} \hat{\sigma}_{\epsilon}^2 \hat{f}(x_0) \int K(z)^2 dz}$$

where  $\hat{\sigma}^2_{\epsilon} = \sum_i w_{i0,h} \hat{\epsilon}^2$  and  $\hat{f}(x_0)$  is the kernel density estimate at  $x_0$ 

- Since we know that there is bias, if we use  $h_{opt}$ , this CI will suffer from  ${\bf undercoverage}$
- On option is to undersmooth. By pick a bigger h, the bias goes to zero, the square of the bias will converge faster than the variance

## An alternative is to bootstramp CI's

Consider the following routine proposed by Yatchew.

- lacktriangle Use CV to find the optimal bandwith. Call this  $\lambda$  and the estimated function  $f_{\lambda}$
- 2 Reestimate f with using a wider bandwidth  $\bar{\lambda} = 1.1\lambda$  (oversmoothing)
- 3 Reestimate f with using a narrower bandwidth of  $.9\lambda.$  Get undersmoothed residuals  $\hat{\epsilon}_i$
- **4** Center residuals and use **parametric** boostrap to generated B samples  $y_i^b = \hat{f}_{\bar{\lambda}}(x_i) + \hat{\epsilon}_i^b$
- **5** Now estimate  $\hat{f}_{\lambda}^b(x_0)$  using the **original**  $\lambda$
- **6** Can obtain 95% CIs from 0.025 and 0.975 quintiles of  $\hat{f}_{\lambda}^{B}(x_{0})$

Seminonparametric (=Flexible) Regression

- Linear model won't fit well when true relationship is nonlinear
- But fully flexible models may require a lot of data
- Alternative is to replace X with M transformations of  $h_m(X)$
- Then model  $f(X) = \sum_m \beta_m h_m(X)$

Charlie Murry & Richard L. Sweeney

Multivariate

Local linear

Basis Expansions

### Series or sieves

- This is a parametric approximation that becomes more accurate as the sample size increases
- Idea: we add regressors when we have more data, eventually providing an arbitrarily close approximation to the true regression function
- Polynomial Example:  $m(x; \beta_K) = \sum_{i=1}^K \hat{\beta}_i x^j$
- Given K, just estimate model using OLS
- In practice, you'll want to choose K using leave-one-out cross validation.

Note that simple polynomials often perform poorly in some parts of the data!

FIGURE 5.1. The top left panel shows a piecewise constant function fit to some artificial data. The broken vertical lines indicate the positions of the two knots  $\xi_1$  and  $\xi_2$ . The blue curve represents the true function, from which the data were generated with Gaussian noise. The remaining two panels show piecewise linear functions fit to the same data—the top right unrestricted, and the lower left restricted to be continuous at the knots. The lower right panel shows a piecewise-linear basis function,  $h_3(X) = (X - \xi_1)_+$ , continuous at  $\xi_1$ . The black points indicate the sample evaluations  $h_3(x_1)_+ = 1, \dots, N$ .

Sweeney

Multivariate

Basis Expansions

Local linear

## Piecewise polynomials (cont)

- We can improve this by adding three additional basis functions:  $h_{m+3} = h_m(X)X$ .
- We can then make it continuous by

$$h_1 = 1$$
 $h_2 = X$ 
 $h_3 = (X - \xi_1)_+$ 
 $h_4 = (X - \xi_2)_+$

Smooth splines

- We can improve this further by increasing the order of the local polynomial
- A common option is cubic splines:

$$h_1 = 1; \quad h_2 = X; \quad h_3 = X^2$$
  
 $h_4 = x^3; \quad h_5(X - \xi_1)_+^3; \quad h_6 = (X - \xi_2)_+^3$ 

- This is a six dimensional space: (3 regions) X (4 parameters per region) (2 knots) X (3 constraints per knot)
- In practice people never use higher than cubic
- Picking the knots is more subjective (use CV?)
- Also typically use B-splines (see HTF)

Natural Splines

THF: "We know that the behavior of polynomials fit to data tends to be erratic near the boundaries, and extrapolation can be dangerous. The polynomials fit beyond the boundary knots behave even more wildly than the corresponding global polynomials in that region."

Natural Cubic Splines Add a further constraint that the fitted function is linear beyond the boundary knots

With K knots is represented by K basis functions:

$$h_1 = 1$$

$$h_2 = X$$

$$h_{k+2} = d_k - d_{K-1}$$

where,

$$d_k(X) = \frac{(X - \xi_k)_+^3 - (X - \xi_K)_+^3}{\xi_K - \xi_k}$$

Charlie Murry & Richard L. Sweeney

Multivariate

Local linear

Basis Expansions

Idea: pick knots to minimize RSS

$$\min_{f(.)} \sum_{i}^{N} (y_i - f(x_i))^2 + \lambda J \int (f''(x))^2 dx$$

where  $\lambda$  is a smoothing parameter and f(x) is any twice differentiable function If  $\lambda = \infty$ , this is just OLS (f'' = 0)

# **Smoothing Splines**

Idea: pick knots to minimize RSS

$$\min_{f(.)} \sum_{i}^{N} (y_i - f(x_i))^2 + \lambda J \int (f''(x))^2 dx$$

where  $\lambda$  is a smoothing parameter and f(x) is any twice differentiable function If  $\lambda = \infty$ , this is just OLS (f'' = 0)

Remarkably, THF show that the solution has a unique finite-dimensional maximizer which can be represented as a natural cubic spline with knots at N chosen points.

We'll discuss this shrinkage estimator next week.

Semiparametrics

References

We'll focus on the most commonly used model: the partial linear model

$$y_i = X_i'\beta + g(Z_i) + e_i$$

We are interested in  $\beta$ , but g() is an unrestricted (unknown) function of z. Identification requires Cov[X, g(Z)] = 0

Robinson (1988) showed that we can concentrate this g() out of the model.

Rocie

Semi-

parametrics

References

$$y_i = X_i'\beta + g(Z_i) + e_i$$

where  $e_i = y_i - E[y_i|X_i, Z_i]$ .

References

$$y_i = X_i'\beta + g(Z_i) + e_i$$

where  $e_i = y_i - E[y_i|X_i, Z_i]$ .

Take the conditional expectation

$$E[y_i|Z_i] = E[X_i|Z_i]'\beta + g(Z_i) + E[e_i|Z_i]$$

then note that  $E[e_i|Z_i]=E[E[e_i|X_i,Z_i]]=0$ 

References

$$y_i = X_i'\beta + g(Z_i) + e_i$$

where  $e_i = y_i - E[y_i|X_i, Z_i]$ .

Take the conditional expectation

$$E[y_i|Z_i] = E[X_i|Z_i]'\beta + g(Z_i) + E[e_i|Z_i]$$

then note that  $E[e_i|Z_i] = E[E[e_i|X_i,Z_i]] = 0$ 

Subtractcing yields

$$y_i - E[y_i|Z_i] = (X_i - E[X_i|Z_i])'\beta + e_i$$

References

So this suggests a natural procedure:

- 1. Estimate the conditional expectations  $m_y(z) = E[y_i|Z_i]$  and  $m_x(z) = E[X_i|Z_i]$  separately (and flexibly) for each x using the methods discussed in the previous section.
- 2. Estimate  $\beta$  using OLS on the residuals

$$y_i - \hat{m}_y(z_i) = (X_i - \hat{m}_x(z_i))'\beta + e_i$$

Defense

So this suggests a natural procedure:

- 1. Estimate the conditional expectations  $m_y(z) = E[y_i|Z_i]$  and  $m_x(z) = E[X_i|Z_i]$  separately (and flexibly) for each x using the methods discussed in the previous section.
- 2. Estimate  $\beta$  using OLS on the residuals

$$y_i - \hat{m}_y(z_i) = (X_i - \hat{m}_x(z_i))'\beta + e_i$$

Note: Yatchew (1997) suggest step 1 can be avoided entirely by simply sorting on z, and running the model in first-differences.

For a recent example, Hastings and Shapiro (AER 2018)

Multivariate Local linear

Semiparametrics

# Single-Index Models I

 Assume we are willing to specify that the conditional mean is a scalar function of the linear combination of X's

$$E[y|\mathbf{x}] = g(\mathbf{x}'\beta)$$

- Often we'll assume q() as in logit and probit.
- Instead, note that the conditional mean of a change in  $x_i$

$$\delta \equiv E \left[ g'(\mathbf{x}'\beta)\beta_j \right]$$

 Suggests the average derivative estimator which doesn't require normality assumptions of probit

# Single-Index Models II

• Let  $m(x_i) = g(x_i'\beta)$ .

$$\hat{\delta}_{AD} = -\frac{1}{N} \sum_{i=1}^{N} y_i \frac{f'(x_i)}{f(x_i)}$$

where f(x) is the density of x (see CT 9.7.4)

- More robust, but potentially less efficient if true distribution of  $\varepsilon \sim N(0,1)$ .
- Can use Marginal Rate of Substitution (MRS) to identify  $\beta_k/\beta_l$ .

$$\frac{\partial \left[y|\mathbf{x}\right]/\partial x_{j}}{\partial \left[y|\mathbf{x}\right]/\partial x_{k}} = \frac{\beta_{j}}{\beta_{k}}$$

## Review: What was the point?

- OLS is lowest variance among linear unbiased estimators.
- But there are nonlinear estimators and potentially biased estimators.
  - Everything faces a bias-variance tradeoff.
  - Nearly anything can be written as Kernel.
  - These are easy to implement in big data settings in one or two dimensions, but quickly run into the curse of dimensionality.
  - Semiparametric approaches often a useful middle ground.
